Global distributions of thermal, epithermal, and fast neutron fluxes have been mapped during late southern summer/northern winter using the Mars Odyssey Neutron Spectrometer. These fluxes are selectively sensitive to the vertical and lateral spatial distributions of H and CO₂ in the uppermost meter of the Martian surface. Poleward of ±60° latitude is terrain rich in hydrogen, probably H₂O ice buried beneath tens of centimeter-thick hydrogen-poor soil. The central portion of the north polar cap is covered by a thick CO₂ layer, as is the residual south polar cap. Portions of the low to middle latitudes indicate subsurface deposits of chemically and/or physically bound H₂O and/or OH.

Neutron spectroscopy can be used to survey planetary bodies for hydrogen (1). The epithermal neutron energy range (0.4 eV to about 500 keV) is most sensitive for this purpose. Measurements of thermal (0 to 0.4 eV) and epithermal neutron fluxes also provide unique information about the existence and thickness of deposits of CO₂ (2). Such deposits are expected to cover both Martian polar caps during their respective winter months (3–5), and CO₂ is also thought to blanket the residual south polar cap of Mars (5–7).

A component of the Gamma-Ray Spectrometer (GRS) aboard Mars Odyssey is the Neutron Spectrometer NS (8, 9). For the purposes of our initial global survey of neutrons produced by Galactic cosmic rays that leak away from Mars, we use data collected between 20 March and 18 April, 2002, covering areocentric Sun longitudes between about Lₛ = 345° and 360° (late in southern summer/northern winter). Estimation of the abundance and stratigraphy of hydrogen near the south Martian pole using gamma-ray and neutron data is presented separately (10).

The NS consists of a cubical block of boron-loaded plastic scintillator that is segmented into four individual prismatic-shaped sensors (9). During mapping the four sensors are oriented with one facing down toward Mars, one facing in the forward direction nearly along the spacecraft’s velocity vector, Vₛ, one facing backward, nearly antiparallel to Vₛ, and one facing upward (11). The difference in counting rates between the forward and backward facing sensors is a reliable estimate of the counting rate across the thermal energy band because the backward sensor measures the epithermal and spacecraft components. The downward-facing sensor is covered by cadmium. The combination of its orientation relative to Mars and its position on the spacecraft provides it optimal sensitivity to epithermal neutrons from Mars, with only little neutron background from the spacecraft.

25.7 days of mapping-orbit data were used in the present survey of neutrons from Mars. Maps of thermal neutrons are constructed using the difference in counting rates due to the ²⁷Al(n,γ)²⁸Si reaction registered by the front- and back-facing sensors. Maps of epithermal neutrons were made using the same procedure for counts measured by the downward, cadmium-covered sensor. Maps of fast neutrons used the counts registered in the lowest channel of fast-neutron pulse-height spectra. (9). All four sensors were summed, yielding a measure of the combined flux of fast neutrons coming from Mars and the spacecraft.

The flux of thermal neutrons is highest north of about +80° latitude (Figs. 1A and 2A). This flux distribution is nearly symmetric about the northpole, but has a small equatorial extension that is centered at 330° east longitude. This zone of maximum thermal flux intensity is surrounded by an annulus of relative minimum intensity (blue color in the maps) that extends equatorward to about +55°, with a maximum equatorial excursion to about +45° latitude between 120° and 285° east longitudes (Figs. 1A and 2A).

The thermal flux intensity is also low south of about −55° latitude. There is a small enhancement of thermal flux that is centered at about −87° latitude, between about 325° and 345° east longitude. The large-scale reduction in thermal flux at the southpole has a small equatorward extension to about −50° latitude centered at about 105° east longitude. An overview of the equatorial portions of the thermal maps shows only small relative variations.

The epithermal maps (Figs. 1B and 2B) shows discrete regions of low fluxes. The south-polar region is delineated by a low flux that exists poleward of about −60° latitude but extends equatorward to about −50° latitude between about 75° and 130° east longitude. Although most of the north-polar region also has low epithermal fluxes, a relative minimum occurs near +60° latitude between about 205° and 275° east longitude. A globally similar pattern of epithermal neutron flux is measured using HEND (13).

Equatorward of ±45°, distinct regions of high and low fluxes can be seen. The highest epithermal fluxes come from just north of Argyre Basin and in Solis Planum. Regions of enhanced hydrogen abundance correspond to relative minima in the epithermal flux. They occur in: i) a broad region southwest of Olympus Mons, extending to, and arcing southward and westward around Elysium Mons; ii) a broad area that extends between −30° and +35° latitude and between 355° and 50° east longitude; iii) a small region centered on +5° latitude between 310° and 330° east longitude; iv) a region centered on −7° latitude between 270° and 292° east longitude; and v) a small region centered at +32° latitude and 317° east longitude.
The fast neutron maps in Figures 1C and 2C also show flux variations. Two salient differences compared to the epithermal maps are: i) the north polar region above +60° latitude has a low flux in the fast neutron maps whereas the central portion of the northern cap shows an increase in the epithermal flux; and ii) variations in fast neutron fluxes equatorward of ±60° latitude are lower than those for epithermal neutrons. The similarity of the fast and epithermal maps is quantified in the scatter plot of fast neutron versus epithermal counting rates shown in Figure 3. A linear regression fits the data well, the correlation coefficient is \( R = 0.84 \).

A comparison of the range of thermal, epithermal, and fast neutron flux intensities observed at Mars (Fig. 4) shows that the flux of fast neutrons varies the least. The maximum to minimum fast-neutron flux ratio for Mars is 2.3, which is much larger than that for the Moon, 1.3 (14). Similarly, the range of thermal (epithermal) neutron fluxes from Mars spans a factor of 7.2 (9.2), while that from the Moon, spans a factor of 3 (1.12) (15, 16).

The large divergence between the lunar and Martian epithermal flux histograms and the strong correlation between fast and epithermal neutron fluxes have only one plausible interpretation: The surface of Mars is richer in hydrogen than that of the Moon. Both epithermal and fast flux components are reduced when hydrogen is present because of a reduction in average atomic mass of surface soils (17) and an increase in moderation efficiency by hydrogen (2, 18). The fact that a single parameter characterizes the correlation between fast and epithermal neutrons on Mars (the slope of a linear regression) points to a single cause of the relationship. In fact, a similar regression for the Moon (not shown here) yields a negative slope and a very poor correlation coefficient, \( R = 0.32 \). This conclusion is supported by detection of a strong 2.223 MeV gamma-ray line south of −60° latitude on Mars by the GRS (10).

A quantitative relationship between hydrogen abundance and epithermal counting rates depends on the distribution of hydrogen abundance with depth below the surface (see fig. 11 of (2)). We use principal effort through possible layered models through analysis of all three energy ranges of measured neutron flux intensities and analysis of the measured intensity of hydrogen neutron-capture gamma rays at 2.223 MeV (10). Burial of a thick hydrogen-rich soil below a thin hydrogen-poor dust layer reduces the flux of epithermal and fast neutrons, reduces the unscattered 2.223 MeV gamma-ray line intensity, and induces a double-valued trend in the flux intensity of thermal neutrons with increasing depth of burial (2). As the depth of burial increases, the leakage flux of thermal neutrons first decreases, reaches a minimum flux level, and then increases back to the intensity that is characteristic of the thick dust soil (2). In contrast, the intensity of thermal neutron leakage flux from a single thick surface deposit of hydrogen increases with increasing hydrogen content before decreasing below the flux level characteristic of the soil with no hydrogen.

Both Martian polar regions have enhanced hydrogen content (Figs. 1 and 2). In the south, where it was summer when the data were accumulated, all three energy ranges of neutron flux begin decreasing from their equatorial plateau southward of between −50° and −55° latitude. In the north, where it was winter, all three fluxes begin to decrease northward of about +50° latitude. The neutron data at high latitudes can be explained readily by the presence of near-surface water ice. The Martian regolith has been formed by impact, colian, and other processes, and may be porous and permeable. Ice can condense and persist in regolith pores if the water vapor partial pressure and the maximum annual temperature permit ice stability. If the observed Martian mean atmospheric water vapor is mixed uniformly over the lower atmosphere, then subsurface pore ice that is in diffusive contact with the atmosphere will be stable on annual time scales wherever the temperature is always below about 200 K (19). Thermal calculations show that this condition will be met below depths of just a few tens of cm poleward of ±60° latitude (19–21), consistent with our observations. Subsurface ice at present times can also be a remnant of polar-cap glaciers that were more extensive during previous epochs.

Neither the north nor the south hydrogen epithermal fluxes are symmetric about their respective poles. The equatorial extension of the fluxes was predicted from time-dependent models of the thermal and diffusive behavior of ice in the Martian regolith (20) and predicted to be observable in measured leakage neutron fluxes (2). This agreement further supports the idea that these enhanced hydrogen deposits near both Martian poles are due to subsurface water ice.

The thermal and epithermal flux intensities increase as both poles are approached. Simulations (2) show that this rise in both flux intensities is the signature of a CO₂ ice cap that covers the underlying hydrogen-rich soil. This rise cannot be due to a subsurface water-ice-rich layer that approaches the surface with increasing latitude because that would result in an increase in thermal neutrons and a decrease in epithermal neutrons, contrary to what is observed. The larger increase at the north pole then corresponds to seasonal CO₂ frost that precipitates out of the atmosphere to cover the polar cap during winter (3–7), and the smaller increase at the south corresponds to the CO₂ ice that covers the residual south-polar cap. This last association is confirmed by the offset from the actual southpole of the increase at thermal energies, coincident with the center of the south polar residual cap. The thickness of the CO₂ frost cap in the north is also not symmetric about the pole. It is greatest in both the thermal and epithermal polar maps at about 330° east longitude. This location corresponds to the topographically lowest part of north-polar region (near Chasma Borealis), and hence the densest portion of the overlying CO₂ atmosphere. One might expect enhanced CO₂ frost precipitation under these conditions (22).

The neutron maps reveal variations in the concentration of hydrogen at middle to low latitudes. One prominent region of relatively high hydrogen concentration covers a large fraction of Arabia Terra and extends into Terra Meridiani and Xanthe Terra to the south and west. Another encircles both Amazonis and Elysium Planitia to the south. Relative minima in the epithermal neutron map are centered on the deepest and widest portion of Valles Marineris near the equator between 270° and 300° east longitude, and just north of +30° latitude at about 315° east longitude, at the mouth of Kasei Valles. The concentrations of H₂O-equivalent hydrogen implied by NS observations at low to mid latitudes can be estimated by comparing thermal and epithermal counting rates measured there, with those at a location on Mars where we have reasonable ground-proof knowledge of the hydrogen content of surface soils. For this purpose we choose the site of Viking 1, for which we adopt the water-equivalent hydrogen abundance from (23) of 1%. Our result for Arabia Terra is 3.8 ± 0.6% and 3.5 ± 0.5% at −15° latitude between 180° to 210° east longitude. If the chlorine abundance of surface soils is constant at equatorial latitudes within a factor of 3, then the
measured depression in thermal neutron fluxes within these hydrogen-rich terranes implies a burial depth of about 25 to 30 g/cm\(^2\) below hydrogen-poor soil. We therefore suspect that the variations in \(H\) concentration seen at these latitudes may primarily reflect geographic variations in the amount of chemically and/or physically bound \(H_2O\) and/or \(OH\) by minerals buried beneath a 15 to 20 cm-thick hydrogen-poor dust layer.

The near-surface Martian regolith is expected to be a mix of unweathered and weathered materials. The unweathered material may be relatively coarse-grained and mostly igneous in origin, while weathered material may be mostly fine-grained and dominated by some mixture of palagonite and clays. The ratio of weathered to unweathered material, as well as the dominant grain size, may depend sensitively on what geologic processes have been most important in modifying the upper regolith on regional scales. For example, regions of net accumulation of wind-blown dust may be richer in fine-grained weathered material than regions of net erosion.

The hydrogen content of such a regolith could be high, and also quite variable on regional scales. Infrared spectroscopic observations of Mars have provided clear evidence of either chemically or physically bound water in the IR-sensed surface, with concentrations of a few tenths of a percent to a few percent (24). The Viking GCMS experiment showed evidence for at least 1% chemically bound water in near-surface soil (23). Palagonite and clays can both contain substantial amounts of chemically bound water. And because fine-grained materials—clays in particular—have high specific surface areas, such materials can readily host several percent or more adsorbed \(H_2O\) under Martian near-surface conditions. So while our data do not rule out the possibility of subsurface ice deposits at low to middle latitudes, they do not require them. We suspect instead that the NS data from these latitudes may be revealing the quantity of physically and chemically bound hydrogen in the upper tens of cm of Martian soil that is buried beneath a 15 to 20 cm-thick layer of hydrogen-poor soil. Important sources of the observed geographic variability may include regional variations in regolith grain size and in the ratio of weathered to unweathered material over these depths.

References and Notes
11. This combination of detection directionality and sensor orientation allows neutron fluxes that originate from Mars to be separated from those that come from the spacecraft.
25. The success to date of the Neutron Spectrometer aboard Mars Odyssey owes a great debt to the large teams at Los Alamos National Laboratory, the University of Arizona, Lockheed Martin Astronautics, and Jet Propulsion Laboratory, who through their individual talents, dedication, and hard work, made it all possible. This work was supported in part by NASA and conducted under the auspices of the U.S. Department of Energy.
